The time of origin of the geodynamo has important implications for the thermal evolution of the planetary interior and the habitability of early Earth. It has been proposed that detrital zircon grains from Jack Hills, Western Australia, provide evidence for an active geodynamo as early as 4.2 billion years (Ga) ago. However, our combined paleomagnetic, geochemical, and mineralogical studies on Jack Hills zircons indicate that most have poor magnetic recording properties and secondary magnetization carriers that postdate the formation of the zircons. Therefore, the existence of the geodynamo before 3.5 Ga ago remains unknown.

## INTRODUCTION

Determining the history of the geodynamo before 3.5 Ga ago is limited by the lack of a well-preserved Archean-Hadean rock record. However, the discovery of Hadean detrital zircon grains in metasediments of the Jack Hills, Western Australia (1), opens up the possibility of studying the magnetic history of Earth during its first billion years. In particular, primary ferromagnetic inclusions (e.g., magnetite) in the zircons may contain a thermoremanent magnetization (TRM) that records the paleointensity of the ancient field during primary cooling (2–5).

To preserve such a record, magnetite-bearing zircon crystals must have avoided being heated above magnetite's 580°C Curie temperature over their subsequent histories (3, 6). Furthermore, obtaining accurate paleointensity studies with well-determined ages for bulk zircon grains requires that the grains' natural remanent magnetization (NRM) be dominated by a TRM rather than a secondary crystallization remanent magnetization (CRM) carried by ferromagnetic inclusions formed or altered during aqueous alteration events after zircon crystallization (3, 6).

Two recent studies (7, 8) using single-crystal paleointensity analyses of Jack Hills zircon grains suggested that a geodynamo existed as early as 4.2 Ga ago with a surface field ~0.1 to 1 times that of present-day Earth. However, those studies (7, 8) had three main limitations: (i) The ages of the NRMs in the grains analyzed are unknown (3, 9); (ii) the grains were not shown to contain a TRM rather than a secondary CRM (6, 10, 11); (iii) the studies' grain selection criteria, which targeted grains with NRM intensities  $>10^{-12}$  Am<sup>2</sup>, might inadvertently have excluded zircons that would have recorded the absence of a dynamo (i.e., that carry no magnetization). In addition, there have been no independent studies corroborating their paleomagnetic measurements. The latter issue is particularly important

because Jack Hills zircons have some of the weakest magnetic NRMs measured in the history of paleomagnetism and therefore require exceptionally sensitive magnetometry techniques and stringent contamination controls. To further evaluate the evidence of an early dynamo and address these limitations, we conducted coupled paleomagnetic, geochemical, and mineralogical analyses on Jack Hills detrital zircon grains.

We extracted the zircon crystals from the pebble conglomerate that we sampled in 2012 at the Hadean zircon discovery locality at Erawandoo Hill [site W74 (3, 9)] using nonmagnetic techniques (see Materials and Methods). From these samples, 3754 zircons were washed with HCl acid and mounted in nonmagnetic epoxy, polished to approximately their midplanes, and dated using U-Pb chronometry. Grains found to have U-Pb ages older than 3.5 Ga (a total of 250) were analyzed using backscattered scanning electron (BSE) microscopy, cathodoluminescence (CL) imaging, and Li-ion imaging. BSE and CL images were used to assess the likelihood of secondary CRM by identifying zircon overgrowths, recrystallization zones, metamictization, cracks, and secondary deposits of minerals in void spaces (12). The goal of Li-ion imaging was to constrain the possibility of secondary TRM by providing estimates of the peak metamorphic temperatures experienced by zircons (11).

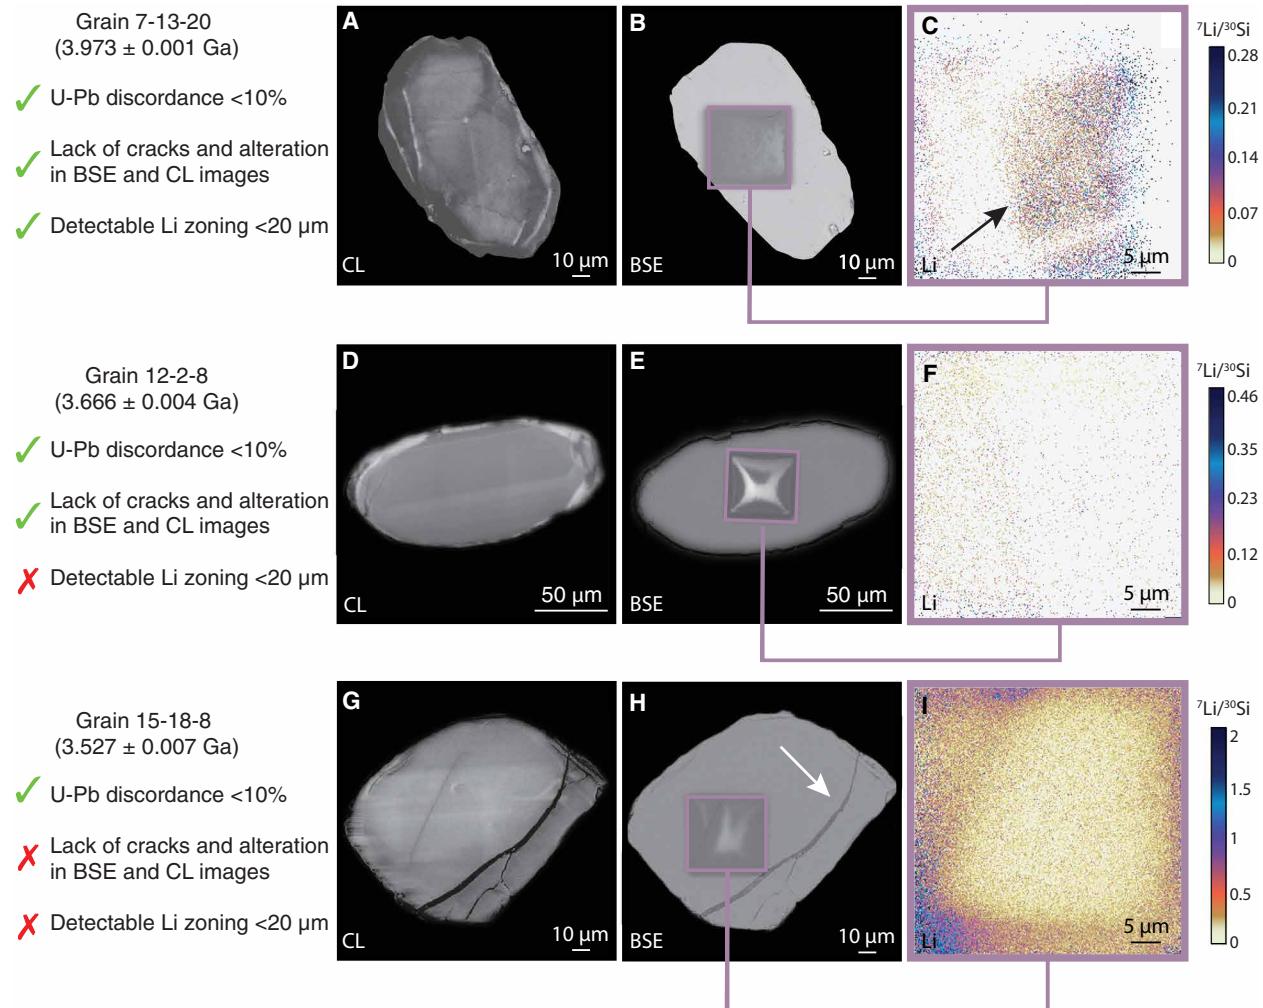

We defined a set of selection criteria that enables the identification of detrital zircon grains minimally affected by secondary TRM and CRM overprints (Fig. 1): (1) U-Pb age discordance <10% (see Materials and Methods); (2) lack of visible cracks, metamictization, and secondary deposits in BSE images and the presence of zonation in CL images interpreted as a primary igneous texture; and (3) presence of detectable primary Li zoning with thickness of <20 μm as observed by Li-ion imaging (11). Criterion (3) indicates the absence of TRM overprints acquired during  $\gtrsim$ 1 million years (Ma) long,  $\gtrsim$ 550°C metamorphic events under the assumption that natural Li diffusivity is similar to experimentally determined values (13). Note that these three criteria are based on measurements that only probe the polished surface of the grain (i.e., do not survey the full grain volume). Furthermore, the analytical methods used for criterion (2) are unable to resolve the <1-μm-diameter single-domain magnetite grains that would carry stable primary magnetization. Thus, these criteria likely are necessary but not sufficient requirements for identifying a zircon with primary NRM.

Of a total of 250 zircon grains, only 3 grains passed all of the above selection criteria. We selected these 3 grains, along with 53 grains

**Fig. 1. Examples of grains that pass and fail the selection criteria.** (A to C) Example of a zircon grain (7-13-20;  $3.973 \pm 0.001$  Ga) that passes all selection criteria: U-Pb age discordance <10%, presence of zonation in CL (A), no signs of secondary deposits on the exposed surface from BSE (B), and <20- $\mu\text{m}$ -thick Li zoning banding (black arrow), indicating that the sample may not have been fully thermally remagnetized since crystallization (C). (D to F) Example of a zircon grain (12-2-8;  $3.666 \pm 0.004$  Ga) that passes some of the selection criteria: U-Pb age discordance <10%, presence of zonation in CL (D), no signs of secondary deposits on the exposed surface from BSE (E), and no observed Li zonation (F). (G to I) Example of a zircon grain (15-18-8;  $3.527 \pm 0.007$  Ga) that fails most of the selection criteria: U-Pb age discordance <10%, absence of igneous zonation (G), presence of secondary mineral filling cracks at the lower right side of the grain (white arrow) (H), and no observed Li zonation (I).

that failed one or more criteria (including 13 subsamples from 6 grains; see Materials and Methods), for subsequent paleomagnetic studies. As a control to confirm that our polishing and ion and electron microprobe measurements do not fundamentally alter the zircons' NRMs, we also analyzed an additional 21 grains in their natural unpolished forms from the same host rocks using nonmagnetic methods, 4 of which were acid-washed. We conducted paleomagnetic analyses on a total of 77 grains.

Given the weak NRMs of the zircons (ranging between  $6.05 \times 10^{-15}$  and  $4.15 \times 10^{-12}$  Am $^2$  before demagnetization), their magnetic moments were analyzed using superconducting quantum interference device (SQUID) microscopy (see Materials and Methods) (14, 15). Following methods previously developed for the Bishop Tuff zircons (2), we obtained paleointensity estimates for the 77 grains using the in-field zero-field zero-field in-field (IZZI) double-heating protocol (16) with partial TRM (pTRM) alteration checks at every other heating step starting at 300°C.

We defined paleomagnetic quality criteria that are permissive compared with those of typical paleointensity studies of younger rocks (see the Supplementary Materials). This is because the overall goal of this study was to establish the presence or absence of a geodynamo at >3.5 Ga ago, which only requires paleointensities with order-of-magnitude uncertainties. Therefore, paleointensity estimates were considered acceptable when a sample (a) had a difference ratio sum  $\leq 25\%$  (17) and (b) gained a moment in the direction of the laboratory field during in-field steps with a maximum angular deviation  $\leq 15^\circ$  (18). Criterion (a) indicates that minimal thermochemical alteration occurred during the paleointensity experiments, while criterion (b) provides evidence that the sample can record an ancient field's direction and intensity (while not requiring the presence or absence of such a field when the zircon acquired its magnetic record). In summary, samples that pass our initial selection criteria and paleomagnetic criteria are candidates for providing a robust constraint on the dynamo at the time of their crystallization. Conversely, samples

with unstable NRM would either indicate the absence of a dynamo (if the sample passes the selection and paleomagnetic criteria) or that the sample is unsuitable for paleointensity experiments (either because of poor magnetic recording properties and/or sample alteration during laboratory heating). Following the paleointensity experiments, we analyzed selected grains with quantum diamond magnetometry (QDM) (19) coupled with transmission electron microscopy (TEM) to elucidate the origin of the magnetic sources within the grains.

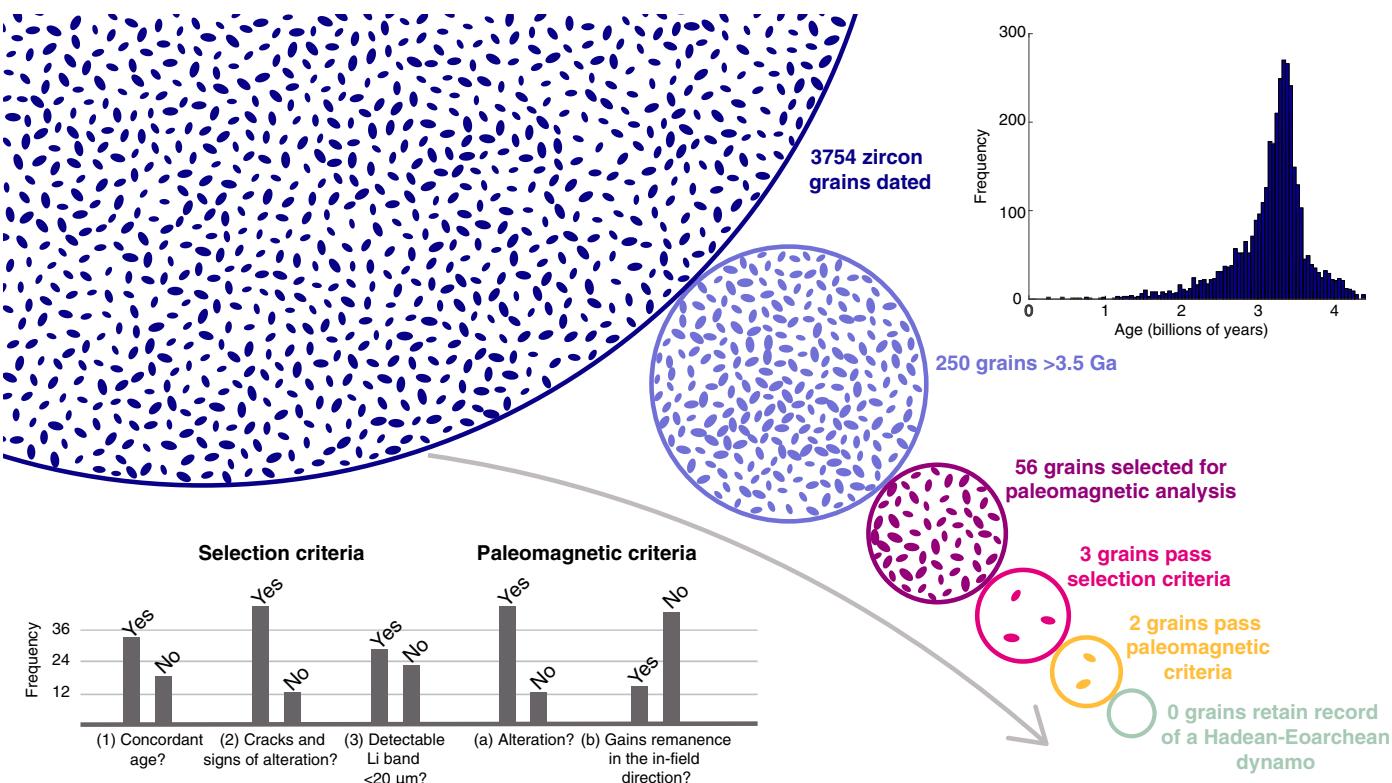

## RESULTS

Of the 77 zircon grains analyzed for paleointensity estimations, only a total of 6 grains passed the two paleomagnetic criteria. We found that 63 of the 77 samples failed paleomagnetic criterion (a), indicating alteration during our experiments. In addition, we found that 54 samples have poor magnetic recording properties, as indicated by their failure of paleomagnetic criterion (b). Among the six grains that passed both paleomagnetic criteria, only two passed all five combined selection and paleomagnetic criteria (Fig. 2). Even if we were to exclude Li zonation as one of the selection criteria, there would be no additional grains that would pass the other selection and paleomagnetic criteria (13). In addition, our analyses of the unpolished control grains confirm that polishing the grains did not increase the incidence of alteration

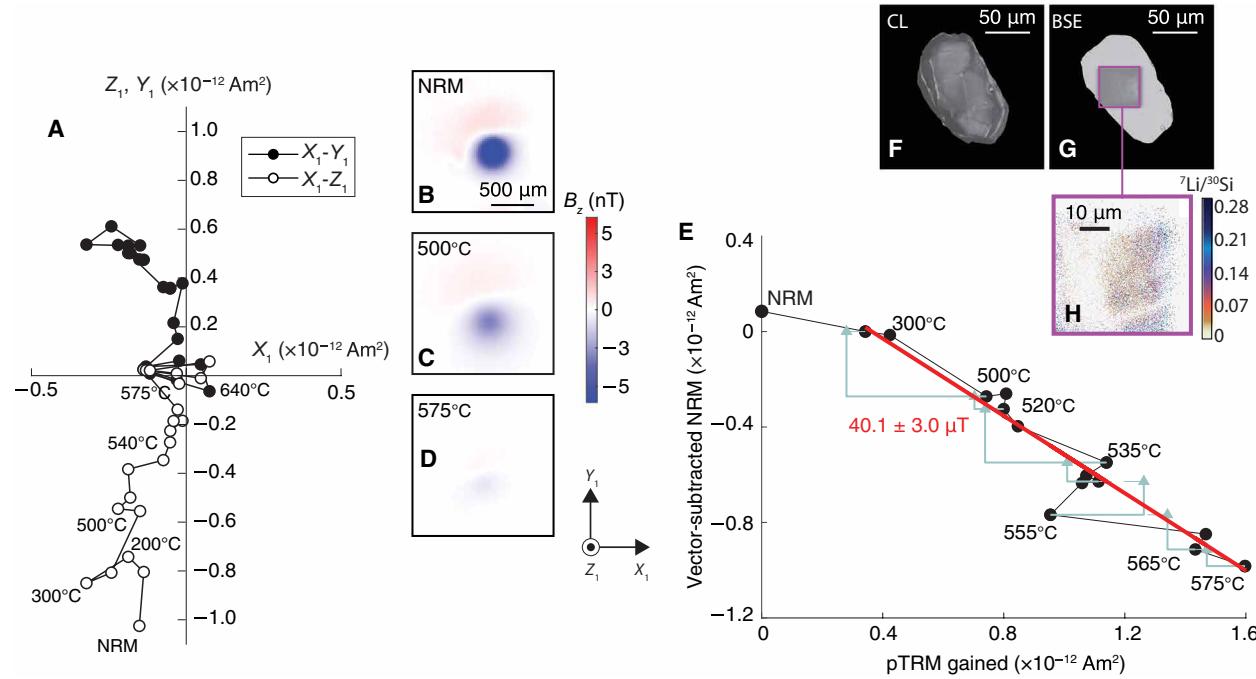

during experiments or the magnetic recording quality (see the Supplementary Materials).

The two grains that passed the five combined criteria were sample 7-13-20, with a U-Pb age of  $3.973 \pm 0.001$  Ga, and sample 8-2-11, with a U-Pb age of  $3.979 \pm 0.007$  Ga. Figure 2 summarizes the selection process starting from the initial 3754 grains and ending at these 2 grains. Figures 3 and 4 show BSE, CL, Li, and paleomagnetic data for these two grains. The two grains each have at least two NRM components. Sample 7-13-20 (Fig. 3) has a low-temperature component that unblocked between room temperature and 200°C, a medium-temperature component that unblocked between 200° and 300°C, and a high-temperature component that unblocked between 300° and 580°C. Sample 8-2-11 (Fig. 4) has a low-temperature component that unblocked between room temperature and 510°C and a high temperature component that unblocked between 510° and 580°C. The 580°C peak demagnetization temperature of the NRMs for both samples indicates that the high-temperature components are carried by nearly pure magnetite.

Figure 5 shows an example of a grain that passes all of the selection criteria but fails all of the paleomagnetic criteria. Most of our grains present NRM demagnetization similar to the one in Fig. 5: unstable demagnetization, thermochemical alteration in the laboratory, and no in-field acquisition of remanence.

**Fig. 2. Summary of zircon selection from the initial 3754 dated grains.** Each circle shows the number of zircon grains remaining after each selection step. The histogram on the top right shows the measured age distribution of the 3754 grains. From the 250 grains that were older than 3.5 Ga, we selected all grains that passed all the selection criteria (3 grains) and an additional set of 53 grains. The histograms at the bottom left show the number of grains that satisfy the various selection criteria [(1) U-Pb age discordance  $<10\%$ ; (2) lack of visible cracks, metamictization, and secondary deposits; and (3) detectable primary Li zoning with thickness of  $<20 \mu\text{m}$ ] and paleomagnetic criteria [(a) the NRM component had a difference ratio sum  $\leq 25\%$ , and (b) the sample gained a moment in the direction of the laboratory field during in-field steps with a maximum angular deviation  $\leq 15^\circ$  over the same temperature range as the NRM component] for the 56 grains selected for paleomagnetic analysis. Only two grains pass all the selection and paleomagnetic criteria. In addition to the 56 polished grains shown here, 21 whole grains were also analyzed paleomagnetically as a control. No grain showed evidence for a Hadean-Eoarchean dynamo.

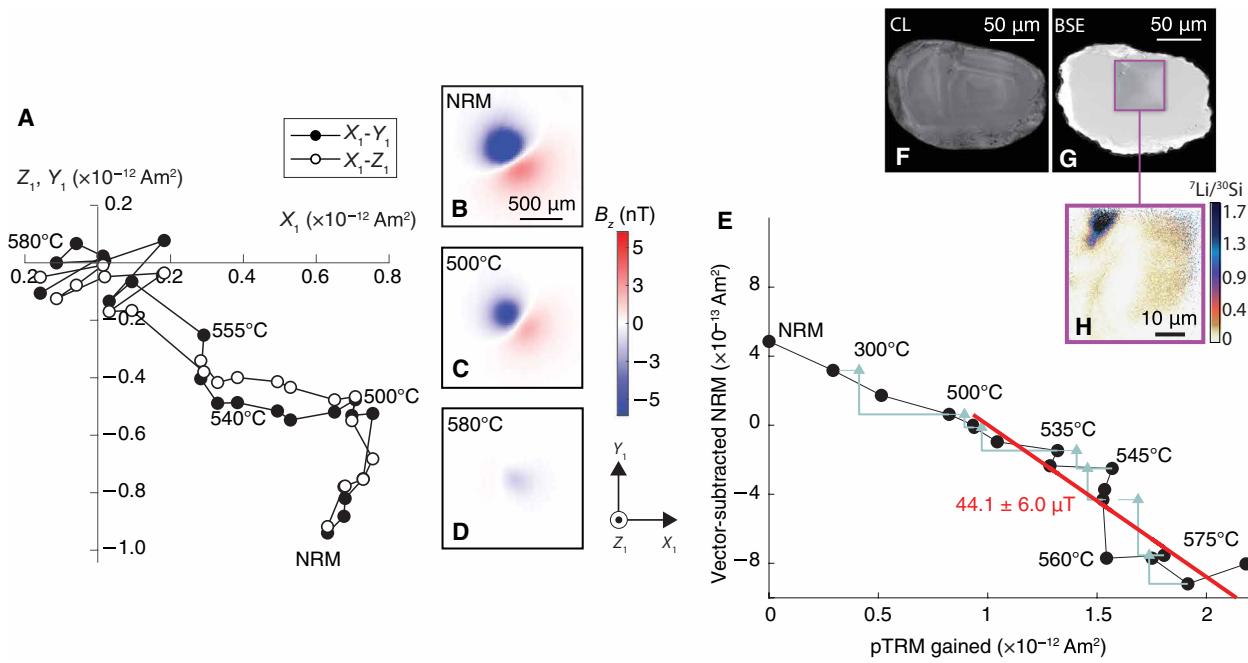

**Fig. 3. Paleomagnetic data for zircon grain 7-13-20 ( $3.973 \pm 0.001$  Ga) that passes all selection and paleomagnetic criteria. (A)** Orthographic projection of NRM vector endpoints during thermal demagnetization. Closed symbols show the  $X_1$ - $Y_1$  projection of the magnetization; open symbols show  $Z_1$ - $Y_1$  projection of the magnetization. Selected demagnetization steps are labeled. **(B to D)** Out-of-the-page magnetic field component ( $B_z$ ) maps measured at a height of  $\sim 360$   $\mu\text{m}$  above the grains obtained with the SQUID microscope for the NRM, 500°C, and 575°C steps. We use a “1” subscript on  $X_1$ ,  $Y_1$ , and  $Z_1$  to denote the fact that the grain orientations during the thermal demagnetization and paleointensity experiments are different from the grain orientations during the BSE, CL, and Li measurements and during the QDM measurements (Fig. 6). **(E)** Vector-subtracted NRM from the 300°C step versus pTRM grained during progressive laboratory heating. Blue triangles show pTRM checks. The red line shows the measurements used to compute paleointensity values (300° to 580°C). **(F to H)** CL, BSE, and Li images of the grains.

Subsequent to the paleointensity studies, grains 7-13-20 and 8-2-11 were analyzed in more detail to elucidate the nature and origin of their ferromagnetic inclusions. First, the isothermal remanent magnetization (IRM) of the samples was imaged with QDM (19) to determine the location of the magnetization sources (Fig. 6). Following this, we used TEM to investigate internal regions with the strongest magnetization. We found no evidence of primary ferromagnetic inclusions. Instead, we observed magnetite crystals (identified using Moiré diffraction interferometry) (10) growing inside voids fed by iron that diffused along the regions of intersecting dislocations. We also identified magnetite crystals with high aspect ratios, crystallographically aligned with the host zircon, and growing along dislocation cores [Fig. 6; see also (10)]. The alignment, aspect ratios, and locations of the magnetite grains within regions of recovery from accumulated radiation damage demonstrate that the grains are secondary in origin (20–22). No evidence has been put forth to support the speculation that they formed by exsolution and/or vapor deposition (8). The presence of secondary magnetite is not linked to alteration during laboratory heating steps, as demonstrated by the fact that these two grains passed paleomagnetic criterion (a) and that they contain voids with a diversity of shapes and sizes that commonly are empty or filled with phases other than magnetite, most commonly baddeleyite and ilmenite (23). The magnetite apparently formed as a result of natural fluid alteration at an unknown time during the last 3.9 Ga, at which time their bulk host zircons would have acquired a secondary CRM.

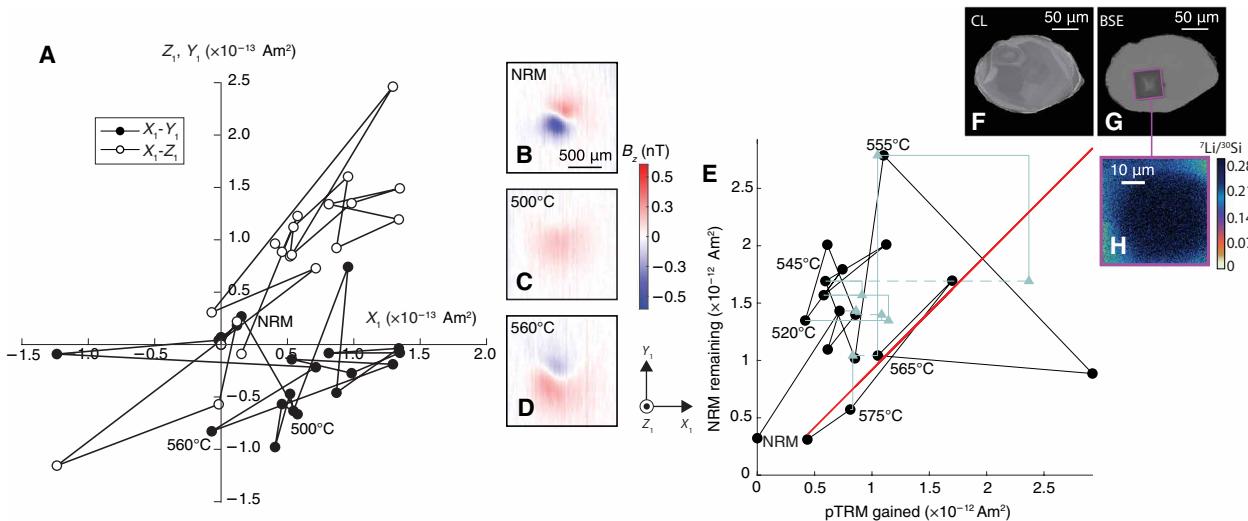

## DISCUSSION

The data presented here suggest that the vast majority of Jack Hills zircons are not suitable for paleointensity studies of the Hadean-Eoarchean magnetic field. In particular, only 2 of 77 grains passed our five selection and paleomagnetic criteria. These two grains yielded results similar to those previously reported for Jack Hills zircons (7, 8) and that were interpreted to be a record of a Hadean-Eoarchean dynamo: initial NRM intensities of  $\sim 1 \times 10^{-12}$   $\text{Am}^2$ , no signs of alteration, and stable NRM demagnetization exhibiting multiple components. However, close examination of both of our grains shows that their magnetic carriers are most likely secondary in origin. Therefore, the ages of their NRMs are unknown and certainly younger than their U-Pb ages. Their multicomponent NRMs are consistent with being CRMs overprinted by pTRMs because of heating events in the Jack Hills outcrop or else by younger CRMs. The presence of a CRM means that the thermal paleointensity experiments, which implicitly assume that the NRM is a TRM, will yield unreliable paleointensity values. We also note that unlike the previous studies (7, 8), we found that the majority of grains analyzed paleomagnetically have poor demagnetization and remagnetization behavior. In conclusion, the existence of the dynamo before 3.5 Ga has yet to be established.

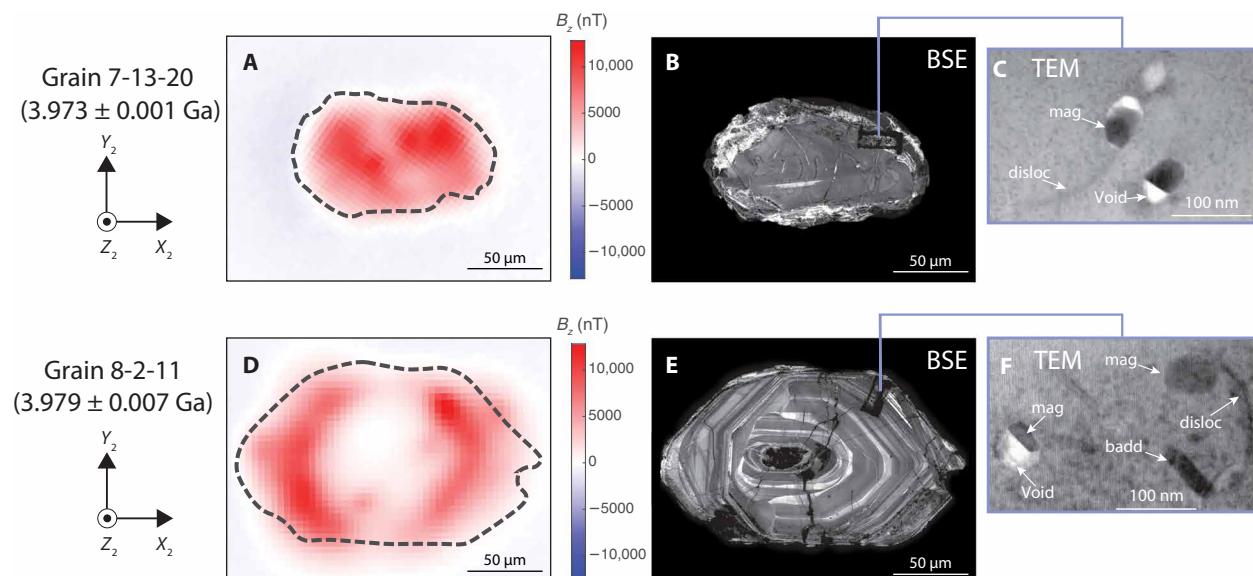

We suggest that the difference in results between our study and that of (7, 8) may be due to our different measurement protocol, in which we washed the grains using concentrated (6 M) HCl to remove considerable amounts of secondary magnetic deposits before paleomagnetic

**Fig. 4. Paleomagnetic data for zircon grain 8-2-11 ( $3.979 \pm 0.007$  Ga) that passes all selection and paleomagnetic criteria.** (A) Orthographic projection of NRM vector endpoints during thermal demagnetization. Closed symbols show  $X-Y$  projection of the magnetization; open symbols show  $Z-Y$  projection of the magnetization. Selected demagnetization steps are labeled. (B to D) Out-of-the-page magnetic field component ( $B_z$ ) maps measured at a height of  $\sim 360$  μm above the grains obtained with the SQUID microscope for the NRM, 500°C, and 575°C steps. We use a “1” subscript on  $X_1$ ,  $Y_1$ , and  $Z_1$  to denote the fact that the grain orientations during the thermal demagnetization and paleointensity experiments are different from those during the BSE, CL, and Li measurements and during the QDM measurements (Fig. 6). (E) Vector-subtracted NRM from the 510°C step versus pTRM grained during progressive laboratory heating. Blue triangles show pTRM checks. The red line shows the measurements used to compute paleointensity values (510° to 580°C). (F to H) CL, BSE, and Li images of the grains.

**Fig. 5. Paleomagnetic data for zircon grain 15-1-7 ( $4.094 \pm 0.005$  Ga) that passes the selection criteria but fails the paleomagnetic criteria.** (A) Orthographic projection of NRM vector endpoints during thermal demagnetization. Closed symbols show  $X-Y$  projection of the magnetization; open symbols show  $Z-Y$  projection of the magnetization. Selected demagnetization steps are labeled. (B to D) Out-of-the-page magnetic field component ( $B_z$ ) maps at a height of  $\sim 360$  μm above the grains obtained with the SQUID microscope for the NRM, 500°C and 580°C steps. We use a “1” subscript on  $X_1$ ,  $Y_1$  and  $Z_1$  to denote the fact that the grain orientations during the thermal demagnetization and paleointensity experiments are different from the grain orientations during the BSE, CL, and Li measurements. (E) NRM lost versus pTRM grained during progressive laboratory heating. Blue triangles show pTRM checks. Red line shows the measurements used to compute paleointensity values (550° to 580°C). (F to H) CL, BSE, and Li images of the grains.

**Fig. 6. Magnetite grains located in dislocations and filling parts of voids postdating igneous formation of the zircon host.** (A to C) Zircon grain 7-13-20. (D to F) Zircon grain 8-2-11. (A and D) QDM maps of the out-of-the-page magnetic field component ( $B_z$ ) of an IRM applied to the grain used to locate magnetic sources at a height of  $\sim 5 \mu\text{m}$  above the samples. We use  $X_2$ ,  $Y_2$ , and  $Z_2$  to denote that the grain orientations for these measurements differ from those during the paleointensity experiments (Figs. 3 to 5). (B and E) BSE images of the grains. The grains were repolished after the paleomagnetic experiments and before these BSE images. Note the difference when compared with the earlier BSE images of the same grains in Figs. 3 and 4; the images here expose several cracks that were not previously visible. (C and F) TEM analyses conducted in the vicinity of the strongest magnetic region of the grain by extracting rectangular focused ion beam sections (from rectangular regions visible in the BSE images). Magnetite ("mag") grains are seen to be forming inside voids that intersect dislocations ("disloc") and growing along dislocation cores that formed during recovery. Magnetite commonly is associated with baddeleyite ("badd"), a secondary product formed after recovery from radiation damage (23), pointing to the fact that the magnetite crystals were not present in the zircon structure when the zircon crystal formed.

measurements, used high-sensitivity magnetic microscopy that enabled measurements of samples with up to 1000 times weaker NRMs, and used QDM and TEM to constrain whether the magnetic carriers are primary in origin. Elucidating the early evolution of the geodynamo may require as yet unidentified detrital minerals that are less prone to radiation damage.

## MATERIALS AND METHODS

### Source location of the samples

Our field work was conducted in the Jack Hills in 2002 and 2012. We separated zircons from five rock samples (named D175C, D175H, D175L, and Cong14c) collected at the Hadean zircon discovery site, location W74 (24), in the Jack Hills, Western Australia, Australia (1), during the 2012 field trip. Table S1 shows the sampling information about the bulk samples and the source material for the grains.

### Zircon separation from host rocks

The five rock samples were manually sledged to gravel size fragments in the Massachusetts Institute of Technology (MIT) Isotope Laboratory. These fragments then were pulverized in a Shatterbox using an all-ceramic grinding vessel and sieved to  $<500 \mu\text{m}$  grain size. The material then was mixed in water in a 4-liter beaker, and the suspended material ( $<5 \mu\text{m}$ ) was decanted; this wash process was repeated 15 times. The remaining sand- and silt-size fraction then was dried under a heat lamp (maximum temperature of  $45^\circ\text{C}$ ). The heavy-mineral aliquot was separated by immersion in a high-density liquid (methylene iodide; specific gravity, 3.32), followed by rinsing in acetone and air drying. Zircon grains then were handpicked under

a binocular microscope using nonmagnetic tweezers. Note that our separation procedures did not involve the standard use of a Frantz isodynamic separator for removing paramagnetic and ferromagnetic minerals, as the high magnetic field of the Frantz would otherwise alter any original NRM that might have been present in the grains.

### Ion and electron microprobe measurements

U and Pb isotopes, backscattered electron microscopy (BSE microscopy), CL, and Li-ion measurements were carried out in the UCLA Secondary Ion Mass Spectrometry (SIMS) Laboratory at the University of California, Los Angeles (UCLA). The samples were transported between MIT and UCLA in magnetically shielded cans. Approximately 400 grains were placed in 10 separate 2.5-cm-diameter epoxy EPO-TEK 301 mounts and polished to approximately their midplanes. Information about bulk rock source for the zircon grains and their respective mount number are compiled in table S1. U and Pb isotopes were measured on a CAMECA IMS 1270 SIMS, using an  $^{16}\text{O}^-$  primary beam, with beam currents of 12 to  $15 \text{nA}$ . A beam diameter of  $\sim 20$  to  $30 \mu\text{m}$  was used. Isotopes measured were  $^{94}\text{Zr}^{2+}$ ,  $^{204}\text{Pb}$ ,  $^{206}\text{Pb}$ ,  $^{207}\text{Pb}$ ,  $^{208}\text{Pb}$ ,  $^{232}\text{Th}$ ,  $^{238}\text{U}$ , and  $^{238}\text{U}^{16}\text{O}$ . The mass-resolving power was  $\geq 5500$ . We used oxygen flooding for improved Pb ionization (25). For the common Pb correction, we used a  $^{204}\text{Pb}$  correction assuming laboratory contamination with environmental Pb from southern California, specifically the San Diego sewage (26), with common  $^{206}\text{Pb}/^{204}\text{Pb} = 18.86$ , common  $^{207}\text{Pb}/^{204}\text{Pb} = 15.62$ , and common  $^{208}\text{Pb}/^{204}\text{Pb} = 38.34$ . An initial  $^{206}\text{Pb}/^{207}\text{Pb}$  ratio survey on 3754 grains was used to identify grains older than 3.5 Ga for all mounts except UCLA 1, 2, and 3; the latter were instead surveyed for grains older than 3.8 Ga. U-Pb measurements and BSE, CL, and

Li images were then acquired from grains that passed this criterion. We calculated the  $^{207}\text{Pb}/^{206}\text{Pb}$  and  $^{206}\text{Pb}/^{238}\text{U}$  dates and inferred the  $^{207}\text{Pb}/^{235}\text{U}$  using the known U isotope ratio ( $^{238}\text{U}/^{235}\text{U} = 137.88$ ). We assigned ages using  $^{207}\text{Pb}/^{206}\text{Pb}$  ratios.  $^{207}\text{Pb}/^{206}\text{Pb}$  and  $^{206}\text{Pb}/^{238}\text{U}$  were used to compute the discordance (27, 28)

$$\left| \frac{\frac{^{207}\text{Pb}}{^{206}\text{Pb}}}{\frac{^{206}\text{Pb}}{^{238}\text{Pb}}} - 1 \right| \times 100\% \quad (1)$$

Table S2 compiles U-Pb measurements for the grains that passed the initial  $^{206}\text{Pb}/^{207}\text{Pb}$  survey. Table S3 contains age and uncertainties for the 77 grains selected for the paleomagnetic experiments. BSE and CL images were acquired with a TESCAN VEGA3 scanning electron microscope equipped with a TESCAN three-channel color CL detector and TESCAN retractable BSE detector (29).

Li-ion images were acquired using a CAMECA IMS 1290 SIMS at the UCLA SIMS Laboratory. We used the Hyperion II radio frequency plasma primary ion source (30) with a 250 to 300 pA  $^{16}\text{O}^-$  beam focused to a  $<1\text{-}\mu\text{m}$  spot size. We rastered the beam over a  $50 \times 50\text{-}\mu\text{m}$  area and recorded 10 frames of ion images of  $^7\text{Li}$  and  $^{30}\text{Si}$ . We used the program WinImage to accumulate the 10 frames each of  $^7\text{Li}$  and  $^{30}\text{Si}$  (image intensity was integrated over all 10 frames), and computed the ratio of the two to get an image of  $^7\text{Li}/^{30}\text{Si}$  intensity. We normalized  $^7\text{Li}$  to  $^{30}\text{Si}$  to account for charging (where the ionization rate may be heterogeneous because of accumulation of charge in the sample as it is continually bombarded with negative secondary ions). The spatial resolution of the images is equivalent to the spot size, so any feature  $>1\text{ }\mu\text{m}$  is not an artifact. Because boundaries on zones are resolved to  $\leq 1\text{ }\mu\text{m}$ , blurring of zones by more than this value means they are actually physically smooth over that length scale. A detectable Li zoning with thickness of  $<20\text{ }\mu\text{m}$  provides evidence that the sample has not been heated  $>550^\circ\text{C}$  for more than 1 million years (11). However, this method might provide an underestimation of the peak temperature experienced by the grains in some cases (13). As discussed in the main text, whether or not the Li band criterion is used to filter our samples does not change the overall outcome of this study. In the Supplementary Materials, we provide evidence that the ion and electron microprobe work measurements did not remagnetize the samples. We also provide the complete set of images taken from all measured grains.

### Acid washing

We previously showed that most Jack Hills zircon grains, when untreated with concentrated (6 M) hydrochloric acid (HCl) acid, have magnetization likely dominated by secondary minerals coating the zircons (6). Therefore, before paleomagnetic measurements, all grains analyzed here (with the exception of four whole grains; see section S5 of the Supplementary Materials) were washed with a 6 M HCl solution for 12 min at room temperature, followed by rinsing in Milli-Q water and air drying. Zircon crystals from samples D175C and D175H were washed with HCl before U-Pb measurements, while grains from D175L and Cong14C were washed with HCl after U-Pb measurements. All grains selected for paleomagnetic measurements were extracted from the epoxy mounts using nonmagnetic tools (Semprex probe needle, lot 18) and washed in 70% sulfuric acid ( $\text{H}_2\text{SO}_4$ ) for 3 hours to remove any residual epoxy deposits before magnetic measurements. During extraction, five samples (18-8-12, 18-15-18, 18-4-8, 1-1-9, and 18-2-12) fragmented into two pieces

and one sample (18-11-13) fragmented into three pieces. All acid washing steps were performed in the MIT Isotope Laboratory clean-room facilities.

### Paleomagnetism

Following HCl and  $\text{H}_2\text{SO}_4$  acid-washing, grains were mounted in pits drilled into Corning Eagle XG glass slides, following similar procedures previously developed for analyzing zircons from the Bishop Tuff (2). Figure S3 shows the overall measuring setup. Optical and magnetic field images of the four glass holders with the grains mounted in the pits before demagnetization are shown in fig. S4. The absolute orientation of the grains was not maintained between mounting in the epoxy for the electron microscopy and ion probe measurements and in the glass mount for paleomagnetic measurements. However, the orientation of the grains and the glass mount was kept fixed throughout the paleomagnetic measurements.

Heating steps were conducted with an ASC Scientific TD48-SC thermal demagnetizer, which provides temperature control with accuracy of better than  $\pm 5^\circ\text{C}$ . An IZZI protocol was used in this experiment (16). The in-field step used a  $50\text{-}\mu\text{T}$  laboratory magnetic field.

Because of the overall weak magnetic moments of the samples (between  $6.05 \times 10^{-15}$  and  $4.15 \times 10^{-12}\text{ Am}^2$ ), NRM measurements were conducted with the SQUID microscope (14) in the MIT Paleomagnetism Laboratory. The configuration used in these experiments, including the sample holder and the mount with the zircon crystals, yields an approximate distance from the SQUID sensor to the midplane of the sample of  $\sim 360\text{ }\mu\text{m}$  (fig. S3). This distance includes the sensor to the window separation ( $\sim 200\text{ }\mu\text{m}$ ), the thickness of the Corning Eagle XG glass left at the bottom of the wells ( $\sim 60\text{ }\mu\text{m}$ ), and half of the size of the grain ( $\sim 100\text{ }\mu\text{m}$ ).

Using SQUID microscopy, we mapped the out-of-the-plane component of the magnetic field of individual zircons at a fixed distance above the sample. Maps were  $3\text{ mm} \times 3\text{ mm}$  in size with spatial sampling of  $25\text{ }\mu\text{m}$ . Magnetic field maps were subsequently inverted for the magnetic moment using previously validated techniques (2, 15). At each demagnetization/remagnetization step, zircon grains with moments  $<1 \times 10^{-13}\text{ Am}^2$  were measured four times and the inverted moments averaged to obtain accurate estimates of their net moments, while stronger magnetic samples were measured only once. When magnetic sources were not observed in our measurements, we assumed a maximum magnetic moment of  $\sim 6 \times 10^{-15}\text{ Am}^2$ , which is the noise floor of the MIT SQUID microscope at this sensor-sample distance. All magnetic measurements, including magnetic maps and processed data, are located in the dataset (see the Supplementary Materials) and will be uploaded to the Magetics Information Consortium (MagiC) database.

### Quantum diamond microscopy

After paleomagnetic measurements, select grains were extracted from the glass mount, placed in epoxy EPO-TEK 301, and polished again. We used the QDM (19) in the Harvard Paleomagnetics Laboratory to constrain the location of the magnetization carriers within the grains. Samples were measured in contact with the sensing diamond after a 0.4-T IRM was applied in the out-of-plane direction using an ASC model IM-10-3 impulse magnetizer. We measured the magnetic field intensity at a height of  $\sim 5\text{ }\mu\text{m}$  above the sample along the [111] direction of the diamond crystal lattice using projective magnetic microscopy with a resolution of 1.17 micrometers per

pixel (19). We isolated the remanent field signal of ferromagnetic grains by measuring the sample successively under two mutually antiparallel 0.9-mT bias fields and computing the out-of-plane magnetic field using a spectral algorithm (15). Figure 6 shows the QDM measurements. The absolute orientation of the grains differed between the SQUID microscopy measurements and these QDM measurements.

### Transmission electron microscopy

TEM was conducted in the Wolfson Electron Microscopy Suite at the University of Cambridge. Our TEM analysis targeted locations based on the QDM maps previously measured. The TEM foil was prepared using a dual-beam focused ion beam microscope FEI Helios NanoLab (Hillsboro, OR, USA) with an area of  $\sim 60 \mu\text{m}^2$  and a depth of  $\sim 7 \mu\text{m}$ . An in-situ lift-out technique was used to site-specifically extract the foil from the place with magnetic signals mapped with the QDM, and a cleanup procedure with low acceleration voltage was used to reduce surface damage of the foil. The TEM sample was examined using a FEI Tecnai Osiris TEM with an extreme Schottky field emission gun. The instrument was equipped with four large-area energy-dispersive x-ray spectrometer detectors, providing a fast chemical compositional measurement. The analysis was carried out at scanning TEM mode at 200 kV, where both bright-field and high-angle annular dark-field images were acquired.

Databases S1 and S2

## 1. Introduction

Here we present more details about our methodology and further discuss their implications. This includes our ion and electron microprobe measurements (Section 2), paleomagnetic measurements (Section 3), paleomagnetic data analysis (Section 4), and the effects of sample polishing (Section 5). We also present data tables containing source blocks and sampling locations for the zircons (Table S1), U-Pb measurements (Table S2), and paleomagnetic analyses (Tables S3-S7).

Throughout this manuscript we have used “ $X_n$ ”, “ $Y_n$ ” and “ $Z_n$ ”, where  $n = 1, 2, 3$ , to represent three different coordinate systems. The grain orientations used during the SQUID microscopy measurements ( $n = 1$ ; Figs. 3-5 and Fig. S6) are different from the orientations during the QDM measurements ( $n = 2$ ; Fig. 6), which are also different than the orientations during the BSE, CL, Li measurements ( $n = 3$ ; Fig. S2).

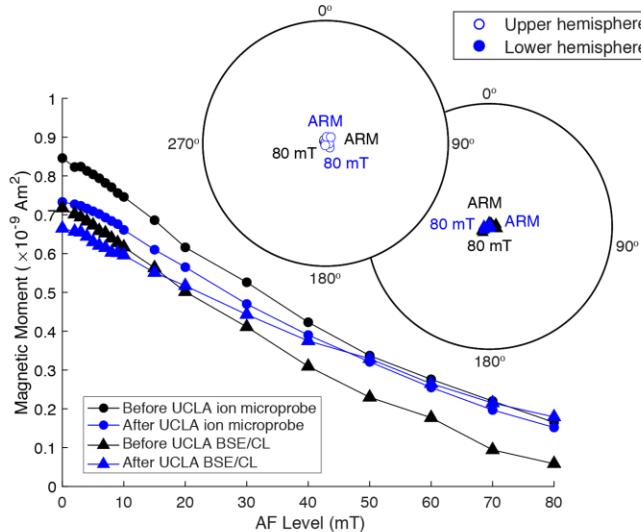

## 2. Ion and electron microprobe measurements do not remagnetize samples

Prior to conducting the U-Pb, BSE, CL and Li measurements, we verified that these measurements do not detectably overprint the natural remanent magnetization (NRM) in the grains. In particular, four zircon crystals from the Mud Tank carbonatite outcrop (31), Northern Territory, Australia, were imparted with an anhysteretic remanent magnetization (ARM) using an alternating field of 200 mT and a 0.4 mT bias field in the Massachusetts Institute of Technology (MIT) Paleomagnetism Laboratory (Figure S1). The samples were then progressively alternating-field (AF) demagnetized to a peak field of 80 mT and their magnetic moments measured using a 2G Enterprises Superconducting Rock Magnetometer model 755 at MIT to infer their ARM coercivity spectra (black circles; Fig. S1). They were then again imparted with the same ARM as before, sent to UCLA to be measured with the ion microprobe and shipped back to MIT. Samples were kept in magnetic shielding cans during transport. At MIT, the samples were again AF demagnetized (blue circles; Fig. S1). Following this, the same procedure was conducted for the BSE and CL measurements (black and blue triangles; Fig. S1).

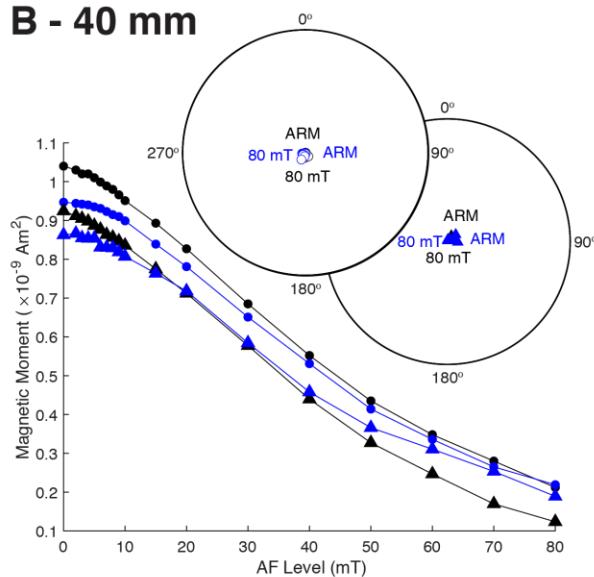

Ion microprobe, BSE and CL measurements of grains A and C were conducted at a measurement height of 20 and 60 mm, respectively, gold coated while grains B and D were measured at a height of 40 and 90 mm, respectively (Figure S1). No magnetic overprint was observed to have been acquired at UCLA (only a slight decay of the magnetization was observed and likely due to viscous decay of the ARM in the shielded can and shielded room). Before the ion microprobe and BSE/CL measurements, the samples were polished resulting in weaker ARM acquisition between the steps (i.e., for each grain, compare first black dot with first black triangle).

We also conducted a second test to assess the effects on the sample’s magnetization of U-Pb measurements and Li imaging using the ion microprobe. The out of the page component ( $B_z$ ) of the NRM of holders UCLA 3 and 7 were measured with the MIT superconducting quantum interference device (SQUID) microscope (14) before and after measurements with the ion microprobe at UCLA (Fig. S2). Samples were kept in magnetic shielding cans during transport as before. No variation in the overall NRM of the samples was observed. These experiments collectively demonstrate that our U-Pb, Li, BSE, and CL measurements do not detectably overprint the NRM of the samples. Section 5 provides further evidence for this.

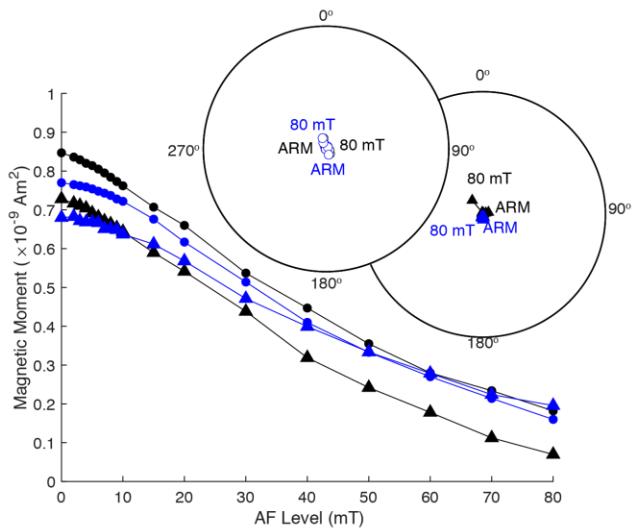

### A - 20 mm - gold coated

**Fig. S1. Test for remagnetization of Jack Hills zircon mounts from electron microscopy and ion probe measurements.** Shown Four zircons from the Mud Tank carbonatite outcrop, Northern Territory, Australia, demagnetization curves, and their respective equal area plots. Samples were initially imparted an anhysteretic remanent magnetization (ARM) using an alternating field of 200 mT and a 0.4 mT bias field, then progressively alternating-field (AF) demagnetized to a peak field of 800 mT and measured using a 2G Enterprises Superconducting Rock Magnetometer 755 in the MIT Paleomagnetism Laboratory (black circles). They were then again imparted with the same ARM as before, sent to UCLA for ion microprobe measurements, and shipped back to MIT. At MIT, the samples were again AF demagnetized (blue circles). The same procedure was conducted for backscattered electron microscopy (BSE) and cathodoluminescence (CL) measurements (black and blue triangles). The demagnetization curves show no significant difference in magnetic behavior before and after the measurements.

**Fig. S2. Test for remagnetization of Jack Hills zircon mounts from ion microprobe measurements.** (A, B) BSE image of epoxy mounts UCLA 3 and UCLA 7 containing 325 and 400 Jack Hills zircon grains, respectively. (C, D) Out-of-the-page magnetic field component ( $B_z$ ) maps of the NRM of two zircon-bearing quartz holders obtained with the SQUID microscope measured at a height of ~250  $\mu\text{m}$  above the grains. We use  $X_3$ ,  $Y_3$  and  $Z_3$  to denote that the grain orientations in the epoxy mount are not the same as those during the thermal demagnetization and paleointensity experiments (Figs. 3-5). (E, F) Magnetic field ( $B_z$ ) of the NRM of two holders obtained with the SQUID microscope at a height of ~250  $\mu\text{m}$  after U-Pb, BSE, CL and Li measurements obtained at UCLA. There are no significant differences in the magnetization before and after imaging the grains.

**Fig. S3. Setup for magnetic measurements using SQUID microscopy.** (A) Photograph of one of the quartz holders. (B) Cross-sectional view of the measurement setup referenced to the coordinate system presented in (A). Figure shows the SQUID microscope chip, the G10 cone, the glass used to mount samples (Corning Eagle XG glass), the quartz powder and the zircon grain. The distance from the SQUID microscope chip to the top of the sample is  $\sim 250 \mu\text{m}$ . The red line represents the top of the glass as shown in (A). We use a “1” subscript on  $X_1$ ,  $Y_1$  and  $Z_1$  to denote this figure orientation is the same as the data shown in Figs. 3, 4 and 5.

### 3. Paleomagnetism

In this section, we discuss general aspects of the grain orientation during the paleointensity experiments, the inversion of non-dipolar magnetic sources, the structure of the supplementary datasets available with this paper, and paleomagnetic criteria. Figure S3 shows the setup for the holders and the samples with respect to the SQUID microscope.

Figure S4 shows photographs of the 4 sample holders used in this experiment overlain with their respective SQUID microscope magnetic maps ( $B_z$ ). Each dark circle represents a hole used to mount one of the 77 zircon grains. The white circles identify non-acid washed zircon grains that were given an isothermal remanent magnetization (IRM) in a field of 0.4 T with an ASC Scientific IM-10 Pulse Magnetizer. Because of their high magnetic moment, these grains were used as references for the location and orientation of the other zircon grains during the experiments.

Figure S5 shows the demagnetization of the IRM of the markers along with Curie temperature indicators for goethite (“goeth”), pyrrhotite (“pyrr”), magnetite (“mag”) and hematite (“hem”). We observe goethite (grains “B” and “L”), pyrrhotite (grains “C”, “H”, “I”, “J”, “K”), magnetite (“C”, “D”) and hematite (grains “A”, “E”, “F”, “G”, “I”) as the major magnetic carriers among the markers. A similar assemblage of ferromagnetic minerals was previously observed in an IRM study of Jack Hills zircons (6) as well as in the pebble conglomerate that hosts the zircons (3). Alteration, characterized by increase of remanence during demagnetization, can also be observed in grains “B”, “H” and “L”. These interpretations are based on the characteristic thermal unblocking temperature of the remanence.

We obtained net magnetic moments from the SQUID microscope maps using a net moment dipole-fitting technique (15). Some of the grains’ magnetic fields were modestly non-dipolar and these data were ignored due to the restrictions of our net moment dipole-fitting technique (15) [18-15-18 (h04) (pTRM check at 555 °C), 18-20-14 (h20) (pTRM check at 555 °C), 18-2-12 (h22) (560 °C Z step, 560 °C I step), 11-12-2 (h24) (560 °C Z step, 565 °C Z step), 15-3-15 (h14) (535 °C I step)]. The exception was sample WGNAW3, for which the majority of measurements were non-dipolar. We fit for dipolar sources for this sample to provide an order-of-magnitude estimate of the magnetic moment variation of the grain.

Included with the supplementary material of this article is a compiled dataset that includes

BSE, CL, Li images, calibrated SQUID microscope maps and fitted data. The dataset is also available in the MagiC database.

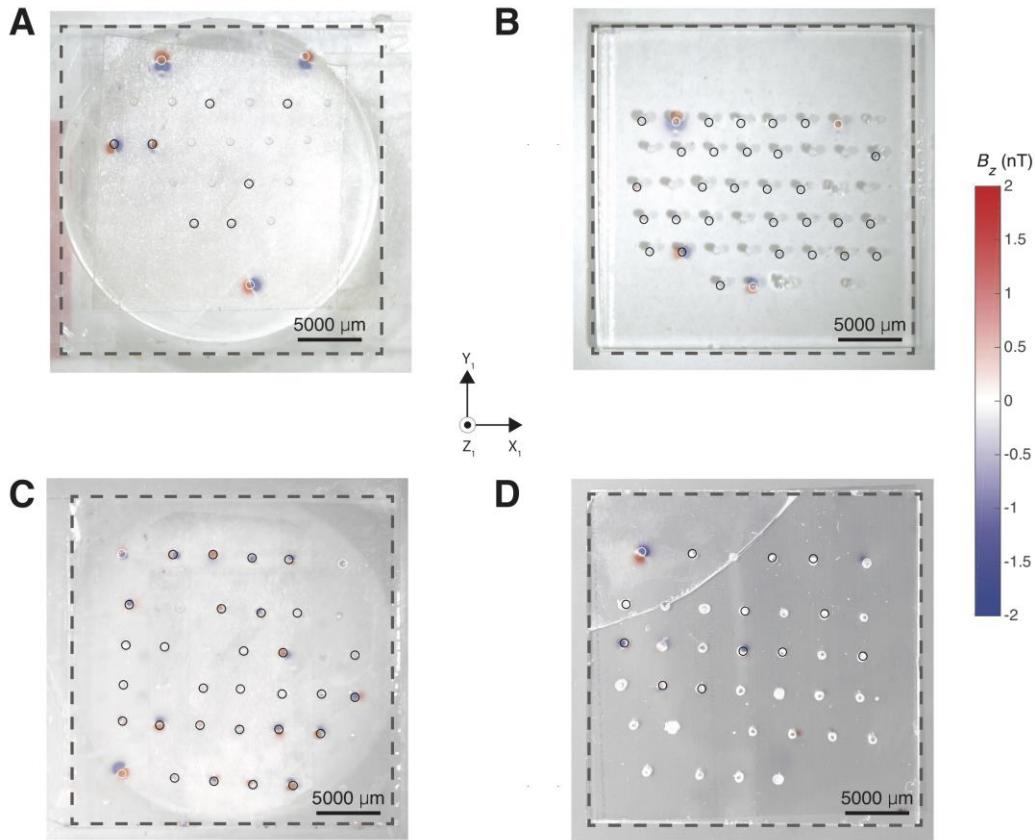

Jack Hills detrital zircon grains are among of the weakest-moment samples ever measured in paleomagnetism. Previous studies have shown that grains with NRMs below  $\sim 10^{-14}$  Am<sup>2</sup> are likely to exhibit noisy demagnetization due to statistics of small numbers of ferromagnetic grains and measurement noise (15, 32). Because we are mainly interested in an order-of-magnitude paleointensity estimate to establish the presence or absence of a dynamo, standard paleomagnetic quality criteria will provide an overly conservative selection of the dataset. For example, none of the samples analyzed here have all  $\delta pTRM_{i,j} \leq 25\%$ , where  $\delta pTRM_{i,j}$  is the difference between the pTRM check in the  $i^{\text{th}}$  temperature step after heating to the  $j^{\text{th}}$  temperature step and pTRM gained in the  $i^{\text{th}}$  temperature step. The exception is sample 080201 (which fails our selection criteria due to the presence of cracks; Fig. S6). Most of the samples have demagnetization similar to what we show in main text Fig. 5. Thus, we considered that a sample could be a reliable paleomagnetic recorder if it did not alter during lab experiments and if it gained magnetic moment in the direction of the bias field during in-field steps of the IZZI protocol. To quantify laboratory-heating alteration, we used the difference ratio sum (DRATS) parameter (17, 33), defined as:

$$DRATS = \frac{|\sum_{i=1}^{end} \delta pTRM_{i,j}|}{x_{end}} \times 100, \quad (2)$$

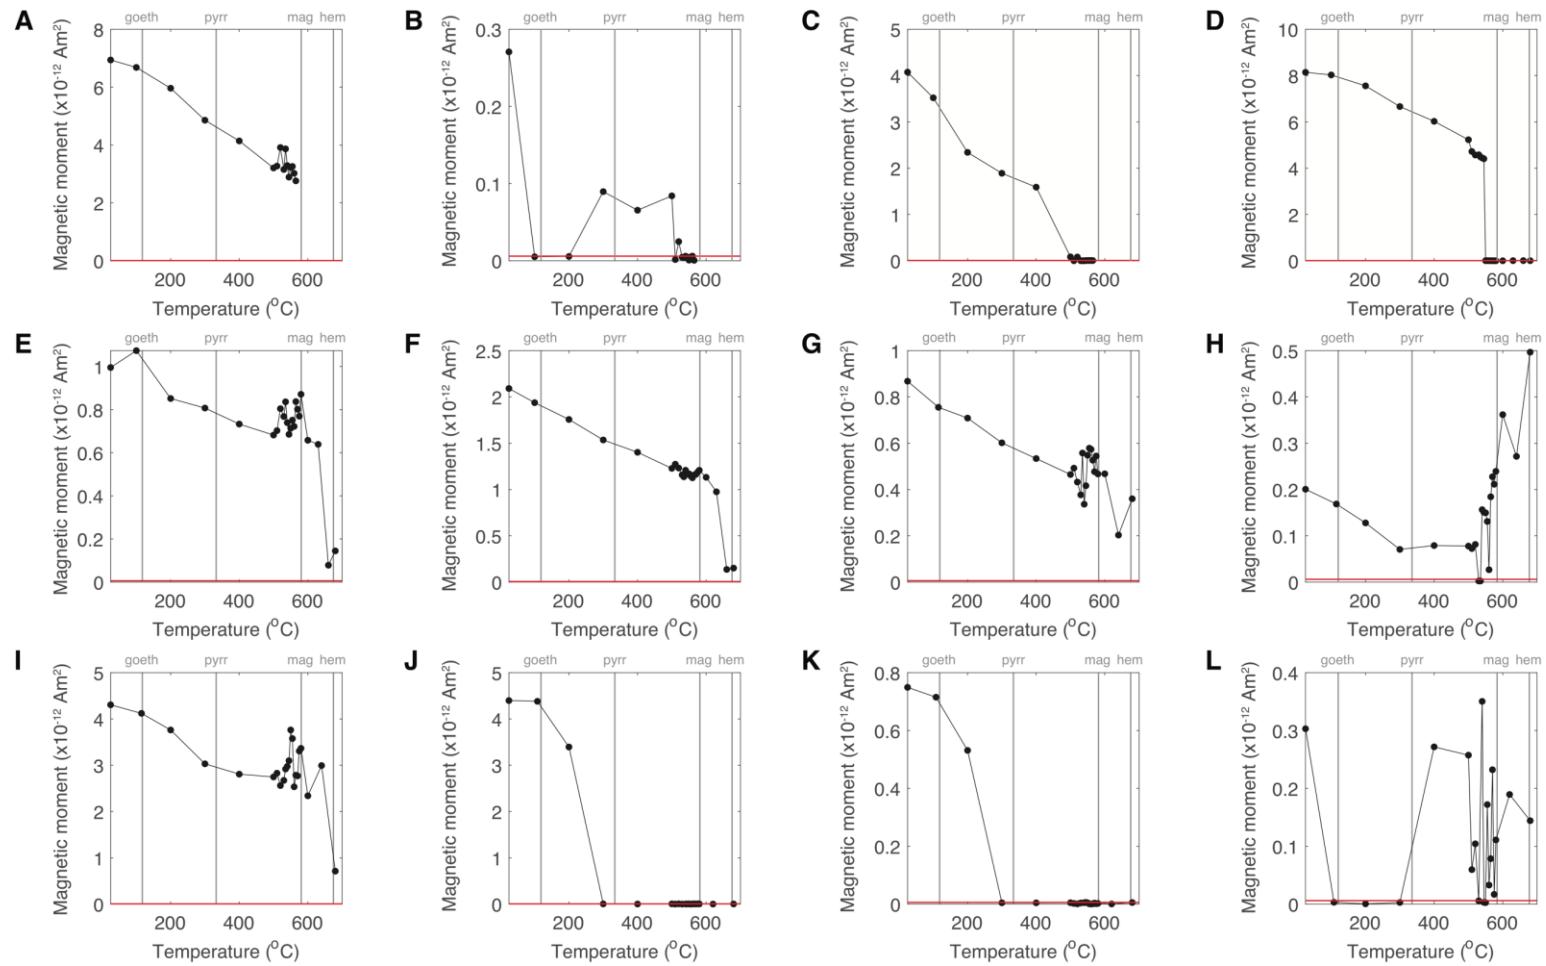

where  $x_{end}$  is the last pTRM gained step. This parameter is an aggregate measure of the success of all the pTRM checks used for the paleointensity estimate. This is useful for considering the effects of low temperature steps for which little pTRM may be gained and, as a result, might yield a large fractional discrepancy between the pTRM check step and the pTRM gained at the same temperature step. We used a threshold value of DRATS  $\leq 25\%$  to identify samples that did not alter during the experiments. Values for all samples are compiled in Table S4.

We used principal component analysis (PCA) (18) to determine whether the in-field components acquired by the grains trend towards Y, as expected from the in-field application during heating steps (which pointed Y in the reference frame in which the paleomagnetic data are presented). This would indicate that the samples acquired magnetization, suggesting that they may be robust paleomagnetic recorders. Zero-field and in-field PCA of the components are presented in Tables S5 and S6. We considered a maximum angular deviation (MAD)  $< 25^\circ$  (18) as indication that the field was adequately recorded. For reference, we also computed the modified PICRIT03 paleomagnetic statistics (33) for all samples analyzed.

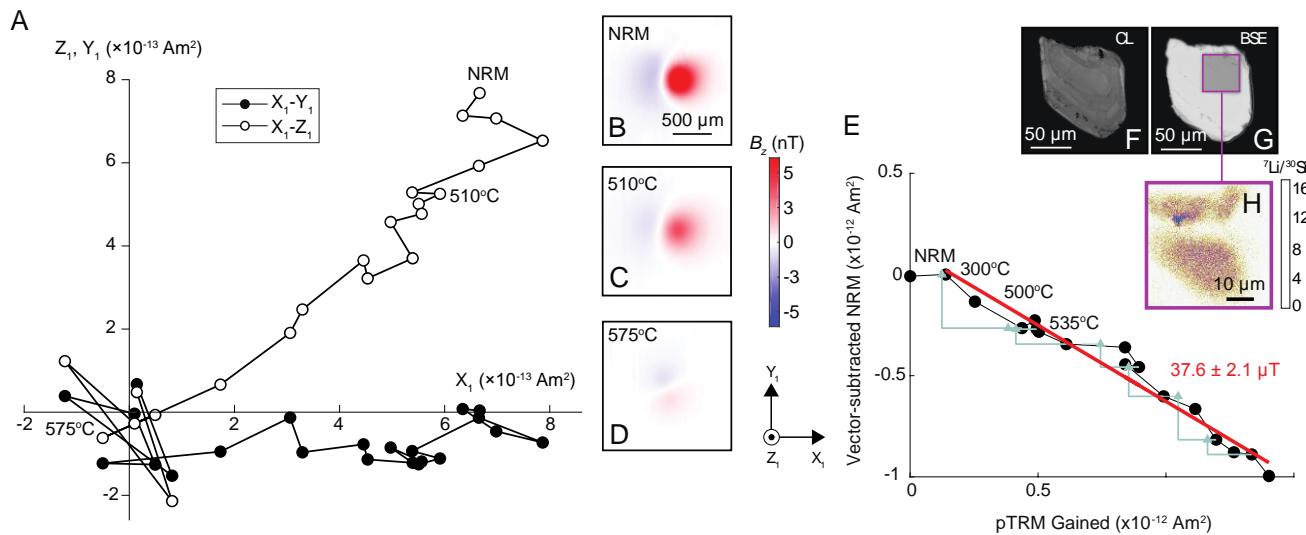

In the studies that previously reported paleomagnetism of Jack Hills detrital zircon grains (7,8), only grains with NRM  $> 1 \times 10^{-12}$  Am<sup>2</sup> were subjected to their paleointensity protocol. We did not use the magnitude of the NRM as a selection criterion for three reasons: (i) ref. (2) obtained reliable paleomagnetic records from the Bishop Tuff zircon crystals with NRM moments as low as  $1.8 \times 10^{-13}$  Am<sup>2</sup> and 40% of our samples have NRM moments above this threshold; (ii) such weak moments are at least 30 times stronger than the sensitivity of our magnetometer (2); (iii) such data selection would be biased against a no-dynamo scenario.

**Fig. S4. Maps of the NRMs of Jack Hills zircons in quartz mounts.** Out-of-the-page field component ( $B_z$ ) of the NRMs of the four sample holders used in this study. (A) Holder C2. (B) Holder E1. (C) Holder F1. (D) Holdeer T1. Measurements were obtained with the SQUID microscope at a height of  $\sim 360$   $\mu\text{m}$  above the top of the grains (Fig. S3). The grain orientations, shown by the compass in the center of the figure, are the same as those shown in Figs. 3-5 and S6. Black circles show where zircon grains were mounted; white circles show where marker zircons were mounted to constrain the location and orientation of each grain analyzed paleomagnetically. The white circles are non-acid washed zircon grains that were given an isothermal remanent magnetization (IRM) in a field of 0.4 T with an ASC Scientific IM-10 Pulse Demagnetizer and used as reference for the location and orientation of the zircon grains during the experiments. We use a “1” subscript on  $X_1$ ,  $Y_1$  and  $Z_1$  to denote the fact that the grain orientations during the thermal demagnetization and paleointensity experiments are different from the grain orientations during the BSE, CL and Li measurements.

**Fig. S5. Compilation of IRM demagnetization of markers used in this study.** Starting from the left, the grey lines denote the Curie temperatures for goethite (“goeth”), pyrrhotite (“pyrr”), magnetite (“mag”) and hematite (“hem”). We observe goethite (grains “B” and “L”), pyrrhotite (grains “C”, “H”, “I”, “J”, “K”), magnetite (“C”, “D”) and hematite (grains “A”, “E”, “F”, “G”, “I”) as the major magnetic carriers among the markers. Thermochemical alteration, characterized by increase of remanence during demagnetization, can also be observed in grains “B”, “H” and “L”. Red line shows the detection limit of our instrument.

**Fig. S6. Paleomagnetic data for zircon grain 8-2-1 ( $3.117 \pm 0.006$  Ga).** (A) Orthographic projection of NRM vector endpoints during thermal demagnetization. Closed symbols show X-Y projection of the magnetization; open symbols show Z-Y projection of the magnetization. (B-D) Out-of-the page magnetic field component ( $B_z$ ) maps at a height of  $\sim 360 \mu\text{m}$  above the grains obtained with the SQUID microscope for NRM, 500°C and 575°C steps. We use  $X_1$ ,  $Y_1$  and  $Z_1$  to denote the fact that the grain orientations during the thermal demagnetization and paleointensity experiments are different from the grain orientations during the BSE, CL and Li measurements. (E) Vector-subtracted NRM from the 300°C step versus pTRM grained during progressive laboratory heating. Blue triangles show pTRM checks. Red line shows the measurements used to compute paleointensity values (300-580°C). (F-H) CL, BSE, and Li images of the grains.

## 5. Effects of polishing samples

A factor that might enhance thermochemical alteration during our paleointensity experiments is the polishing of the grains required for the imaging and dating procedures that occurred prior to beginning the magnetic measurements. Such polishing may have exposed magnetic minerals in the original interior of the zircons to alteration in air, which otherwise would be encapsulated in whole grains. We tested for this effect by conducting double-heating IZZI paleointensity experiments on 21 whole grains zircons (of which 4 were non-acid-washed and the remaining acid-washed) following the same heating and measurement schedule as that used for polished grains. These whole grains were randomly selected from separates from rock sample Cong14c without the use of any selection criteria (see Table S1). We observed that 19 grains altered during experiments (by failing the DRATS requirement described in Section 4), 12 were poor magnetic field recorders (did not gain moment in the direction of the reference field during in-field steps by failing the MAD requirement as in Section 4), and no grain passed the paleomagnetic criteria.

Table S5 provides a comparison of results from non-polished and polished grains. As before, grains that had DRATS values  $\leq 25\%$  were considered to not have significantly altered, while grains that had MAD values  $\leq 15^\circ$  for the in-field magnetic component were considered robust paleomagnetic recorders. Because 0% of unpolished and 11% of polished grains pass the paleomagnetic criteria, we conclude that there is no systematic difference between the suitability of polished grains and non-polished grains for paleointensity analyses.

We can also compare the NRM components of polished and non-polished grains (18). While Section 2 provides evidence that the U-Pb, BSE, CL and Li measurements do not overprint the NRMs of our polished samples, we can use the unpolished grain paleomagnetic dataset (which did not undergo U-Pb, BSE, CL and Li measurements) to further test that conclusion. In particular, we searched for NRM components with MAD values  $\leq 15^\circ$ , obtained from PCA (18). Grains that had a single NRM component with MAD values  $\leq 15^\circ$  totaled 12 (20%) out of 56 for the polished grains, versus 2 (10%) out of 21 for the non-polished grains. Therefore, similarly small fractions of polished and unpolished grains have identifiable NRM components. PCAs of all grains are compiled in Tables S6 (zero-field steps) and S7 (in-field steps).

**Table S1. Information about source blocks for analyzed zircon grains from Jack Hills, Western Australia.** Table includes block sample names, mass, mount names, sampling location (Australian Map Grid 1984 datum) and sampling date.

Block Name	Mass (kg)	Mounts	Sample Location		Sampling Date (MM/DD/YYYY)
			Latitude (°)	Longitude (°)	
D175C	2.6	UCLA 1, 2, 3	-26.16664	116.99148	7/31/2012
D175H	8.6	UCLA 6, 7, 8	-26.16664	116.99148	8/3/2012
D175L	2.0	UCLA 11, 12	-26.16664	116.99148	8/3/2012
Cong14c	2.8	UCLA 15, 18	-26.16674	116.99134	7/31/2012

**Table S2. Compilation of U-Pb ages for grains that passed initial  $^{207}\text{Pb}/^{206}\text{Pb}$  survey.** The first column gives the samples name. The second and third columns give the  $^{207}\text{Pb}/^{206}\text{Pb}$  age in million years (Ma) and the standard error (1 sigma). The fourth and fifth columns give the  $^{206}\text{Pb}/^{238}\text{U}$  in million years (Ma) and the standard error (1 sigma). The sixth and seventh columns give the  $^{207}\text{Pb}/^{235}\text{U}$  in million years (Ma) and the standard error (1 sigma). The eighth column gives the percentage of radiogenic  $^{206}\text{Pb}$ . The ninth and tenth columns show the ratio of  $^{206}\text{Pb}/^{238}\text{U}$  values corrected for common Pb ( $^{206}\text{Pb}^*/^{238}\text{U}$ ) and the standard error (1 sigma). The eleventh and twelfth columns show the ratio of  $^{207}\text{Pb}/^{235}\text{U}$  values corrected for common Pb ( $^{207}\text{Pb}^*/^{235}\text{U}$ ) and the standard error (1 sigma). The thirteenth and fourteenth columns show the ratio of  $^{207}\text{Pb}/^{206}\text{Pb}$  values corrected for common Pb ( $^{207}\text{Pb}^*/^{206}\text{Pb}^*$ ) and the standard error (1 sigma). The fifteenth column shows the correlation of concordia ellipses of the grains that passed the initial  $^{206}\text{Pb}/^{207}\text{Pb}$  ratio survey calculated according to ref. (34). Dashed values ("--") represent no measurements were obtained. AS3 standards are the standard measured for each mount.

Sample name	$^{207}\text{Pb}/^{206}\text{Pb}$ Age (Ma)	1 s.e. (Ma)	$^{206}\text{Pb}/^{238}\text{U}$ Age (Ma)	1 s.e. (Ma)	$^{207}\text{Pb}/^{235}\text{U}$ Age (Ma)	1 s.e. (Ma)	% radiogenic $^{206}\text{Pb}$	$^{206}\text{Pb}^*/^{238}\text{U}$ 1 s.e.	$^{207}\text{Pb}^*/^{235}\text{U}$ 1 s.e.	$^{207}\text{Pb}^*/^{206}\text{Pb}^*$ 1 s.e. **Table S3. General information about the 77 grains paleomagnetically analyzed in this study.** The first column shows grain name (grains that fragmented have hole number “hxx” next to the name to different the fragments). The second column shows source rock. The third and fourth columns show age of the grain in Ma calculated from  $^{207}\text{Pb}/^{206}\text{Pb}$  and the standard error (1 sigma) in Ma. The fifth column shows the age of the grain in Ma calculated from  $^{206}\text{Pb}/^{238}\text{U}$ . The sixth column shows the discordance calculated between  $^{207}\text{Pb}/^{206}\text{Pb}$  and  $^{206}\text{Pb}/^{238}\text{U}$  according to equation (1). Seventh column shows if sample lack of visible cracks, metamictization and secondary deposits in BSE images and the presence of zonation in CL images interpreted as a primary igneous texture (“PASS” if sample passes the criterion; “FAILS” if sample fails the criterion; “?” if we do not have data for the criterion). Eighth column shows if sample has detectable primary Li zoning with thickness of  $<20\text{ }\mu\text{m}$  as observed by Li-ion imaging (“PASS” if sample passes the criterion; “FAILS” if sample fails the criterion; “?” if we do not have data for the criterion). The ninth column shows if sample was acid washed or not (“PASS” if sample passes the criterion; “FAILS” if sample fails the criterion; “?” if we do not have data for the criterion). The tenth column shows if samples passed the selection (“PASS” if sample passes the criterion; “FAILS” if sample fails the criterion; “?” if we do not have data for the criterion). The eleventh column shows if samples passed the selection criteria ignoring the Li criterion (“PASS” if sample passes the criterion; “FAILS” if sample fails the criterion; “?” if we do not have data for the criterion). The twelfth column contains the NRM in  $\text{Am}^2$ . The thirteenth, fourteenth, fifteenth and sixteenth columns show maximum pTRM check, and maximum pTRM check above 500°C, 530°C and 550°C. The seventeenth column shows the DRATS calculated according to equation (2). The eighteenth column shows the MAD calculated from in-field steps. The nineteenth column shows if sample passes the paleomagnetic criteria (the NRM component had a difference ratio sum (DRATS)  $\leq 25\%$  (15) and the sample gained a moment in the direction of the laboratory field during in-field steps with a maximum angular deviation (MAD)  $\leq 15^\circ$  over the same temperature range as the NRM component; “PASS” if sample passes the criterion; “FAILS” if sample fails the criterion; “?” if we do not have data for the criterion). The twentieth column shows if samples passed both the selection and paleomagnetic criteria (“PASS” if sample passes the criterion; “FAILS” if sample fails the criterion; “?” if we do not have data for the criterion). The twenty-first column shows if samples passed both the selection and paleomagnetic criteria ignoring the Li criterion (“PASS” if sample passes the criterion; “FAILS” if sample fails the criterion; “?” if we do not have data for the criterion). Dashed values (“-”) represent no measurements were obtained. Shaded columns constitute the three section and two paleomagnetic quality criteria.

Sample name	Source rock	Age $(^{207}\text{Pb}/^{206}\text{Pb})$ Selection Criterion (1)	Age unc. (Ma)	Age $(^{206}\text{Pb}/^{238}\text{U})$ Selection Criterion (1)	Discordance (%) Selection Criterion (1)	BSEM and CL no cracks? Selection Criterion (2)	Li band? Selection Criterion (3)	Acid wash? **Table S4. Summary of the paleomagnetic data for the 77 samples paleomagnetically analyzed in this study.** The first column shows the grain name (grains that fragmented have hole number “hxx” next to the name to differentiate the fragments). The second column shows the paleointensity fit range. The third and fourth columns show the calculated paleointensity and the standard error of the paleointensity (1 sigma). The fifth, sixth, seventh, eighth and ninth columns show, respectively, the paleointensity parameters  $f$ ,  $\beta$ ,  $q$ , maximum DRAT and CDRAT. Dashed values (“-”) represent no measurements were obtained or no magnetic signal from the grain.

Sample name	Fit range (°C)	Paleointensity (μT)	Std. error (μT)	$f$	$\beta$	$q$	Max. DRAT	CDRAT

**Table S5. Comparison of paleomagnetic data between 56 polished grains and 21 unpolished grains.** First row shows the values for range of the NRM. Second row shows the number of grains that fail paleomagnetic criterion (a) (DRATS  $\leq$ 25) showing that they altered. Third row shows the number of grains that fail paleomagnetic criterion (b) (sample gained a moment in the direction of the laboratory field during in-field steps with a maximum angular deviation (MAD)  $\leq$ 15° over the same temperature range as the NRM component) showing that they are bad recorders. Fourth row shows the amount of grains that pass both criteria. Fifth row contains the total amount of grains. These results ignore the selection criteria and only consider the paleomagnetic data. We do not observe any significant difference in the resulting data between non-polished and polished grains.

	Unpolished	Polished
NRM range ( $\text{Am}^2$ )	$3.01 \times 10^{-14}$ to $2.23 \times 10^{-12}$	$6.05 \times 10^{-15}$ to $4.15 \times 10^{-12}$
Alteration (fails paleomagnetic criterion "a")	19 (90%)	44 (79%)
Poor magnetic recorders (fails paleomagnetic criterion "b")	12 (57%)	42 (75%)
No signs of alteration (passes paleomagnetic criterion "a") and robust recorder (passes paleomagnetic criterion "b")	0 (0%)	6 (11%)
Total	21 (100%)	56 (100%)

**Table S6. Summary of principal component analysis and maximum angular deviation (MAD) of the 77 samples analyzed here.** The first column shows grain name (grains that fragmented have hole number “hxx” next to the name to differentiate the fragments). The second column contains component name (“LT” for low temperature component, “MT” medium temperature component, “HT” high temperature component). The third, fourth and fifth columns show, respectively, the range of the component, MAD value and if the component was forced through the origin (“Y” if forced).

Sample name	Component	Range (°C)	MAD (°)	Origin forced?
K1	LT	025-400	12.1	
	MT	400-510	4.8	
	HT	510-565	7.4	Y
K2	HT	025-565	3.8	Y
2-9-19	LT	025-400	35.3
